(Received 10 May 2023; revised 18 July 2023; accepted 19 July 2023)

Multi-cell positron traps have been proposed to accumulate and store large numbers of positrons (e.g., $>10^{10}$). This design arranges lines of Penning-Malmberg traps (“cells”) on and off the magnetic axis in a vacuum chamber in a uniform magnetic field. Confinement considerations impose additional constraints on the magnetic field beyond the usual on-axis homogeneity requirements. These requirements are discussed. A prototype magnetic field and associated coil geometry is suggested to achieve good single-component plasma confinement in all cells. Experimental confinement data as a function of electrode alignment with respect to a nominally uniform magnetic field are also presented. These results are related to the field-alignment considerations of the magnet design study.

1. Introduction and overview

Magnetic fields with tailored spatial profiles are important in many areas. Examples include medical imaging (Westbrook 2014), plasma and fusion research (National Academies of Sciences, Engineering, and Medicine 2021), and the confinement of antimatter (Fajans & Surko 2020). Regarding the latter, positrons have proven useful for scientific and technological applications ranging from fundamental atomic physics to materials characterization (Schultz & Lynn 1988; Wahl & Buchanon 2002; Gidley et al. 2006; Charlton & van der Werf 2015; Cassidy 2018; Fajans & Surko 2020). However, sources of positrons provide relatively small particle fluxes as compared, for example, to their electron antiparticle counterpart; and this has severely limited their utility.

One unfulfilled technical capability is a practical device to accumulate and store large numbers of positrons (e.g., $>10^{10}$) for many minutes or longer. This paper discusses considerations relevant to tailoring the magnetic field for such a device. An immediate need for a high-capacity positron trap is to provide bursts of positrons to create a magnetically confined electron-positron (“pair”) plasma (Pedersen et al. 2012; Stoneking et al. 2020). Such a plasma is expected to have unique properties. For example, it will be useful for fundamental plasma physics studies and relevant in astrophysical settings (Stoneking et al. 2020; Goodbread & Liu 2022).

The most common confinement device for positrons is the Penning-Malmberg (PM) trap (Driscoll et al. 1986; Malmberg & Driscoll 1980; Murphy & Surko 1992; Danielson et al. 2015; Fajans & Surko 2020). It consists of a set of cylindrical electrodes arranged axially in a uniform magnetic field. The magnetic field provides radial confinement, while axial confinement of the single sign of charge is achieved by electrostatic potentials on the end electrodes. However, as the trap is filled, the plasma space charge increases.

† Email address for correspondence: csurko@ucsd.edu
Confinement in PM traps, while good, is not perfect. The radial particle excursions in the strong space-charge electric fields lead to plasma heating and enhanced outward diffusion of the particles across the magnetic field (Malmberg & Driscoll 1980; Danielson & Surko 2006a).

Currently, confinement of over $10^9$ positrons has been achieved in a single PM trap (Jorgensen et al. 2005; Fitzakerley et al. 2016; Blumer et al. 2022). This was done by trapping positrons using a buffer-gas trap and then stacking pulses in a UHV trap in a large magnetic field where the particles cool by cyclotron radiation. The number of trapped positrons $N$ increases linearly with the number of pulses, and stacking can be done with near-unity efficiency.

However, as the number of confined positrons $N$ is increased, the required confinement voltage (which scales as $N/L$, with $L$ the plasma length) and the radial space-charge electric field increases. This leads to unacceptable levels of positron heating and positronium formation, where the latter is a virulent positron loss process, even in an otherwise good vacuum. Thus, the increasingly large voltages required on the end electrodes limit the maximum particle capacity of a single PM trap to $\sim 10^{10}$ particles, which has been achieved for electrons (Danielson et al. 2006b). Other confinement considerations limit $L$ in typical traps to from one tenth to a few tenths of a meter (Danielson et al. 2006b; Hurst et al. 2019).

References Danielson et al. (2015) and Fajans & Surko (2020) describe the many factors that can affect the confinement of single-component plasmas in PM traps. Unfortunately, there are no quantitative predictions for the confinement of single-component plasmas in the practical PM traps used in actual experiments, and so the available guidance is empirical. While electrostatically trapped particles can also contribute to a lack of confinement (Notte & Fajans 1994; Kabantsev & Driscoll 2002), this effect, which appears as if it can possibly be mitigated by use of a multi-ring electrode structure (Mohamed et al. 2013) and colloidal graphite coated electrodes (Fajans & Surko 2020), is not considered further here.

To circumvent the space-charge constraints on $N$, it has been proposed to achieve the required accumulation and storage of large numbers of positrons in a so-called “multi-cell trap” (MCT) (Surko & Greaves 2003; Danielson & Surko 2006a) by arranging many PM traps (i.e., “cells”) in series, and lines of these cells in parallel, in a common vacuum system and immersed in the uniform field provided by a solenoidal superconducting magnet. The benefit of this MCT design is supported by a variety of experimental and theoretical work (Malmberg & Driscoll 1980; Malmberg et al. 1988; Danielson & Surko 2006a; Danielson et al. 2015; Fajans & Surko 2020). Various aspects of the technology required for an MCT for positrons have now been developed, including high-efficiency, off-axis transfer and good off-axis confinement, and further work is in progress (Danielson et al. 2006b, 2013; Baker et al. 2015; Hurst et al. 2019; Singer et al. 2021; Singer 2023).

Presented here is a discussion of the design considerations for the magnetic field for such an MCT. They are intended to optimize the alignment of the field with respect to the electrode axes and to avoid magnetically trapped particles, both of which are believed to lead to better particle confinement and hence improved positron storage capabilities (Danielson et al. 2015). Also presented here are the results of a complementary experimental study of confinement as a function of magnetic field alignment in a PM trap, and these results are related to the magnetic field design study.
2. Electrode structure for a multicell trap

A current MCT design calls for PM cells 100 mm to 300 mm long and arrangements of one or a few concentric rings of these cells (Baker et al. 2015; Hurst et al. 2019). The magnetic field $B_0 = 5 \text{T}$ is chosen to provide the required cyclotron cooling (cooling rate $\propto B^2$), since adequate cooling is critical to the required long confinement times (Hurst et al. 2019; Fajans & Surko 2020). Two possible versions of such a trap to confine positron numbers $N \geq 10^{10}$ are illustrated in Fig. 1: Design (i) is a 21-cell trap consisting of 3 banks of 7 storage cells (SC); and Design (ii) is a 19-cell trap with one bank of 2 concentric rings of storage cells arranged around a center cell. In both designs, the first ring of cells is approximately 25 mm off axis; and in (ii), the second ring of cells is 50 mm off axis.

A “master cell” (MC) is placed at the end of each arrangement of storage cells. It is used to move plasmas, accumulated in a separate positron trap, off-axis to fill the storage cells using autoresonant excitation of the diocotron mode (Fajans et al. 1999; Danielson et al. 2006b; Baker et al. 2015; Hurst et al. 2019). Either electrode arrangement would occupy a total volume of one to a few liters of the vacuum system for a trap for $N \geq 10^{10}$ positrons.

Ideally, one would like the magnetic field in this volume to be uniform to a high degree of accuracy and uniformly aligned with the axes of the confinement electrodes, since such field errors in PM cells are known to degrade plasma confinement and complicate off-axis injection (Baker et al. 2015).

3. Magnetic field considerations

There are interrelated requirements for the confining magnetic field for a practical multi-cell trap for positrons. One would like to avoid magnetically trapped particles, which are predicted to lead to poor particle confinement (Fajans 2003; Eggleston et al. 2006). This can occur if there is a maximum in the magnetic field (i.e., a “magnetic mirror”) in the trapping region. This effectively divides the particles into two separate populations, trapped and untrapped, by a separatrix in velocity space. This, in turn, results in increased transport and poor confinement. This can be prevented by arranging the field $B(z)$ to be slightly non-uniform with no maximum (i.e., no “magnetic mirror”) in the confinement region of the trap, where $z$ is oriented in the direction of the axis of
symmetry. Assuming the magnetic field is symmetric about \( z = 0, r = 0 \), this requirement is the constraint:

\[
\begin{align*}
\frac{\partial B_z(z)}{\partial z} &< 0 \quad \text{for} \quad z < 0, \\
\frac{\partial B_z(z)}{\partial z} &> 0 \quad \text{for} \quad z > 0,
\end{align*}
\] (3.1)

within the confinement region.

However, the fact that \( \frac{\partial B_z(z)}{\partial z} \) is nonzero and that many plasmas are in cells off the magnetic axis leads to a significant radial component of \( B \) off-axis as determined by the solution to \( \nabla \cdot B = 0 \). Assuming cylindrical symmetry, the radial component of \( B \) will be

\[
B_r = \frac{1}{2} \left( \frac{\partial B_z}{\partial z} \right) r. \tag{3.2}
\]

Such nonzero values of \( B_r \) result in the bending of the off-axis magnetic field lines. While the effects of magnetic field alignment on PM trap confinement have been discussed for straight field lines misaligned with respect to the electrode axis (see Fine 1988, Section 6.3; Hart 1991; Mitchell 1993, Section 3.4); to our knowledge, the effects of continuously bent field lines, such as those described here, on transport has not been considered previously. This is potentially important for the MCT, since good confinement is required for a high-capacity trap. Note that the field nonuniformities considered here are radial, as opposed to the azimuthal (i.e., magnetic multipole) asymmetries which have been discussed previously (Fajans et al. 2005, 2008).

Assuming \( B_z \approx B_0 \), which is easily fulfilled for the situations considered here, and writing \( dr \approx \theta dz \), where \( \theta \approx B_r/B_0 \ll 1 \) is the angle of the field line with respect to the \( z \) axis, the radial deviation of the field line at axial position \( z \) from that at \( z = 0 \) will be

\[
r(z) - r(0) = \int_0^z \frac{B_z(z')}{B_0} \, dz', \tag{3.3}
\]

where \( r(0) \) is the center of a storage cell. The rms deviation

\[
< \Delta r > \equiv \left[ \langle (r - \bar{r})^2 \rangle \right]^{1/2}
\] (3.4)

of the field line from its average position \( \bar{r} \) over an interval from \( z = 0 \) to \( d \) is a measure of its straightness. Field alignment is often discussed for a straight field line oriented at angle \( \theta \) to the \( z \) axis. In this case the correspondence is

\[
\theta = \frac{\sqrt{3}}{d} < \Delta r >. \tag{3.5}
\]

As discussed above and illustrated in Fig. 1, a trap with approximately 20 cells could be: Design (i) configured with 3 banks of 7 cells displaced axially for 21 cells [Fig. 1(a)], or Design (ii) one bank of 19 cells of the same length, with one center cell plus a ring of 6 and a second ring of 12 SC [Fig. 1(b)]. There are several considerations as to which design is best. The electrodes in (i) are easier to connect to voltage sources, while (ii) affords better pumping, which is of great importance for large values of space charge (Hurst et al. 2019).

The constraint of Eq. 3.1 would require a longer region of \( \frac{\partial B_z}{\partial z} \neq 0 \) for Design (i), leading to increased field-line bending as per Eqs. 3.2 and 3.3. Since avoiding magnetically
Magnetic field considerations for a multi-cell Penning-Malmberg trap for positrons

Figure 2. Coil geometry for the different MCT magnet designs with the MCT electrodes at the center. The corresponding coil dimensions for each case are listed in Table 1.

trapped particles is assumed to be important, Design (ii) is preferred over Design (i). Thus Design (ii) [cf. Fig. 1(b)], with 19 cells, is chosen for further study. However, Design (i) does have distinct advantages: It avoids having to move, and position, plasmas farther off axis and wiring concentric rings of electrodes, one inside the other. At this early stage of MCT development, it is unclear which design will prove best; and so Design (i), while not considered further here, is still considered to be a good candidate.

In the following, we assume storage cell electrodes with 12 mm ID and 2 mm thick walls separated radially by a minimum distance of 6 mm. Thus the center of the first ring of 6 electrodes is at \( r = 22 \) mm, the second ring of 12 electrodes is at \( r = 44 \) mm, and the confinement volume of this second ring of SC extends to \( r = 50 \) mm.

4. Magnet design

Considered here are possible magnetic field coil configurations for the design (ii) MCT. The outer diameter of the electrode structure, the accompanying vacuum vessel and additional space in the cryostat for thermal insulation to allow for superconducting operation put a lower limit on the inner radius of the solenoid, which is assumed here to be \( R = 130 \) mm. The extent of the tailored magnetic field region is determined by the combined length of the master cell and storage cells (assumed total length 500 mm, as shown in Fig.1) and the outermost extent of the confinement volume of the furthest off-axis cell (\( r = 50 \) mm). This volume, with \( r \leq 50 \) mm and \( z \leq \pm 250 \) mm will be referred to as the ‘confinement region’ in which the goal is to produce a magnetic field configuration that optimizes confinement.

Magnetic field computations were done using COMSOL Multiphysics, version 5.6, using a 2D axisymmetric model with the static magnetic fields interface. The magnetic coils described below are assumed to be homogeneous, multi-turn coils using 1 mm diameter superconducting wire. A generic cross sectional schematic of these solenoids is shown in Fig. 2. The parameters of the main solenoid (length \( L \), inner radius \( R \), winding thickness \( T \) and number of turns \( N \)) and trim coils (\( r \), \( t \), \( l \), and \( n \), respectively; and spacing \( s \)) for each design case are listed in Table 1. The coils are modeled in COMSOL as conductors with an electrical conductivity of \( 10^{20} \) S/m. The current density for the Cases 1, 2, and 3 in Table 1 was assumed constant at approximately 100 MA/m², which is consistent with other coil designs in the literature (Li et al. 2020). The current density for Case 4 is approximately a factor of two larger.
Table 1. Magnet parameters related to Fig. 2 with spatial dimensions in millimeters. Listed are the dimensions of the central solenoid, R, L, and T; and the trim coils, r, l, t, and s; the number of central-solenoid turns N, number of trim coil turns n, current I, and the central field strength \( B_0 \).

4.1. Solenoid with end correction coils

To illustrate the considerations involved, the field profile of a simple solenoid, with dimensions shown in Case 1 of Table 1, is shown in Figure 3(a) as dashed black line. The field maximum at \( z = 0 \) of this solenoid-only configuration poses an issue in creating a magnetic mirror within the confinement region. Furthermore, this prominent curvature in \( B \) leads to a significant contribution of radial field component. For these reasons, corrections coils are required to achieve the design requirements. The resulting values for \( \Delta B_z / B_0, \Delta B_r / B_0, < \Delta r > \), and \( \theta \) for the simple solenoid and corrected cases are summarized in Table 2.

Table 2. Measures of field-line bending in the confinement region of the MCT magnet, including the fractional variations of \( B_z \) and \( B_r \) in percent, the rms deviation in \( r \) along a field line at \( r = 50 \) mm, and the angular deviation \( \theta \) from \( z = 0 \) to 250 mm. For case 4, these metrics are evaluated over a confinement region of \( z = 0 \) to 120 mm.

Additional windings at the ends of solenoids are often implemented to improve overall homogeneity (Loney 1966). They are used here to remove the central peak in \( B \) at \( z = 0 \) [cf. Fig. 3(a)]. The number of turns and physical dimensions of the coils in \( r \) and \( z \) can adjusted to meet the design criteria given by Eq. 3.1 and to minimize \( |B_r| \) to the extent possible. An example of such a magnet design is Case 2 in Table 1. The general features of this design, with discrete trim coils, is similar to that discussed in Ref. (Dorbin et al. 2020). Optimization was done by following guidelines from Loney (1966, Sec. 7) as well as trial and error: first imposing the constraint of Eq. 3.1, and then tuning the coil parameters to minimize \( B_r \) and hence \( < \Delta r > \). The resulting solution is neither unique nor completely optimized. While more sophisticated optimization techniques are available (Li et al. 2020, Sec. 2.1), the approach described above proved to be adequate to meet the design goals.

Shown in Fig. 3 are the results for this design including the locations \( B(r, z) \) of the field lines at the radii of 25 mm and 50 mm where the rings of off-axis cells would be located for design (ii), and for comparison, outside of the confinement region at 75 mm. The axial profile has weak maxima at both ends of the confinement region, as shown in Fig. 3 (a) and (b): there is a minimum at \( z = 0 \), and \( B \) increase continuously toward
Magnetic field considerations for a multi-cell Penning-Malmberg trap for positrons

Figure 3. Magnetic field of the end-corrected solenoid (Table 1, Case 2) operating at a current of 102.5 A. (a) on axis profile over extent of the end corrected magnet (solid) compared with simple solenoid (dashed); (b) z component of field in the confinement region at radii (-) $r = 0$, (--$25$ mm, (-) $50$ mm and (---$75$ mm; (c) radial components of field at these radial locations; and (d) the corresponding deviations $\Delta r(z)$ of the field lines centered at these radii, where $\Delta r$ is symmetric about $z = 0$.

either end of the confinement region, thus eliminating magnetically trapped particles. The radial component of field shown in Fig. 3(c) has a reversed sign compared to that of the simple solenoid due to the change in sign of $\delta B_z/\delta z$. The variations of $B$ for this design are $\Delta B_z/B_0 = 0.12\%$ and $\Delta B_r/B_0 = 0.05\%$ within the confinement region.

The maximum amplitude of $B_r$ in the confinement region is $2.7$ mT at $r = 50$ mm. Using Eq. 3.5, the corresponding angle $\theta$ of a straight line from $z = 0$ to $z = 250$ mm connecting the ends of the field line in this interval is $\theta = 6.2 \times 10^{-5}$ rad, a factor of 15 improvement over the simple solenoid. This value is comparable to the alignment of $\theta = 2.1 \times 10^{-4}$ rad measured for a single PM trap (Singer et al. 2021), and a subsequently determined value of approximately $5 \times 10^{-5}$ rad for an MCT (Singer 2023).

4.2. Optimized correction coils

The overall homogeneity and amplitude of $B_r$ can be further improved by shifting the trim coils away from the main solenoid in both radius and axial position (Loney 1966; Li et al. 2020) as illustrated by Case 3 of in Table 1. The results are shown in Fig. 4. The variations of $B$ for this design are much smaller than for Cases 1 and 2: $\Delta B_z/B_0 = 0.04\%$ and $\Delta B_r/B_0 = 0.001\%$ within the confinement region.

As shown in Fig. 4(a); the on-axis profile is largely flat in the confinement volume. Although this configuration moves the maxima in $B_z$ [Fig. 4(b)] and $B_r$ [Fig. 4(c)] closer to $z = 0$, they reside outside of the $\pm 250$ mm axial extent planned for confinement, which still fulfills the constraint of Eq. 3.1. The maximum amplitude of $B_r$ is $0.5$ mT at $r = 50$ mm in the confinement region and the corresponding angle $\theta$ of a straight line from $z = 0$ to $z = 250$ mm connecting the ends of the field line is $\theta = 1.9 \times 10^{-5}$ rad. This is a factor of 48 (3) lower than the simple (end corrected) solenoid. Additional details of the field profile over the extent of the confinement region are shown in Fig. 5, where the fractional variation $\Delta B/B_0$ and the distribution of $B_r$ are mapped in a 2D color scale.
Precise positioning of the trim coils would be required to realize these calculated results. In practice, variations in superconducting wire diameter and imperfections in wire placement within the magnet can lead to additional field variation. Furthermore, the forces due to energizing a superconducting magnet can be very large and even lead to deformation of the windings (Ren et al. 2010). For this design case there is an expected $4.0 \times 10^5$ N of axial force on the trim coils and $3.0 \times 10^8$ Pa of radial pressure on the main solenoid, as calculated by integration using COMSOL. To gauge the feasibility of this design against foreseeable manufacturing imperfections, the simulation was repeated with one of the trim coils axially displaced from the optimized position by offsets between $\pm [0.5, 5]$ mm. While these perturbations led to asymmetric profile in $B_z$, no maxima emerged in the confinement region thus still satisfying the design intent of excluding magnetic mirrors. For the largest offset, the amplitude of $B_r$ is changed by $\sim 1$ mT on the side of the misaligned coil, which is still less than that of the end corrected solenoid.
Magnetic field considerations for a multi-cell Penning-Malmberg trap for positrons

Figure 6. (a) Profile of the on-axis magnetic field (blue dots) overlapped with the electrode structure of the prototype MCT. It has one on-axis ($S_2$) and two off-axis ($S_1$, $S_3$) storage cells which are shown on the right and a master cell on the left. (b) An enlarged view of the on-axis storage cell $S_2$. The electrodes are denoted $S_{2,1}$ to $S_{2,5}$. The blue arrow shows the direction of a magnetic field line which is tilted in respect to the electrodes wall and directly connected to the electron emitter. The red circles show the dicotron orbits for plasmas confined in $S_{2,2}$ and $S_{2,5}$, and the black stars indicate the initial position of the loaded plasmas. The dashed black line shows the center position of the $S_{2,2}$ orbit when projected onto the orbit of $S_{2,5}$. The distance $\delta$ between the centers of the orbits and $\Delta z$ are used to determine the angle of misalignment $\theta$.

5. Experimental study of the effect of alignment on particle confinement

To our knowledge, beyond Refs. (Fine 1988; Hart 1991; Mitchell 1993) for PM traps and (Heinzen et al. 1991) for Penning traps, there is little quantitative data for the effect of magnetic field alignment on particle confinement. In the course of a recent experiment to develop an MCT, the experimental apparatus described in Refs. Singer et al. (2021); Singer (2023) is equipped with the capability to study confinement of an electron plasma in a 3.1 T field as a function of the misalignment of the confinement electrodes. Experiments are described here to study this effect for an on-axis storage cell to illustrate the deleterious effects of misalignment. No data are presently available for plasmas in off-axis cells.

The experimental results described in this section study the misalignment of assumed straight magnetic field lines oriented at an angle $\theta$ to the trap electrodes, rather than the bent field lines discussed above. While not directly comparable, the experimental results illustrate the important effect of such misalignments on particle confinement.

The prototype MCT has three storage cells (one on- and two off-axis) and a master cell and is placed in a superconducting magnet with a 3.1 T field (Singer et al. (2021)). The magnet was modeled in COMSOL, since the details of the magnet windings were unavailable (due to the age of the device). This was done by trial and error fitting to
the experimentally measured on-axis near-field profile. The resulting specifications of the magnet are given in Table 1, Case 4.

Confinement as a function of misalignment was studied in the on-axis storage cell S2, using electrons. The structure is purposely misaligned by shifting the vacuum tube which holds the trap within the bore of the magnet, which is kept fixed. The plasmas span the region inside electrodes S2.2 to S2.4 with a -300 V confinement potential applied to S2.1 and S2.5. They have a length of 50 mm and an initial radius of 0.5 mm. For the well aligned case, the shot-to-shot reproducibility is about 1%. However, due to the change of the emitter position with respect to the trap when adjusting δ, the reproducibility is as much as 7% for the values of δ shown in Fig. 7. The misalignment also changes the boundary conditions for the fill process. This results in a change in the amount of charge in the plasma as δ is changed. Thus the cases for which data is presented here vary by about 7% about the initial mean of $N \sim 2.7 \times 10^8$ particles.

The radial distance δ between the centers of S2.2 and S2.5 was measured using the $m = 1$ diocotron mode technique described in Refs. Aoki et al. (2004); Singer et al. (2021). In Fig. 6(b), the distance δ is defined as the distance between the centers of the diocotron orbits in S2.2 and S2.5 when projected onto one plane at the same magnetic field. The orbits are separated by an axial distance of $\Delta z = 69$ mm. Converted to an angular alignment, $\delta = 203 \mu$m is equivalent to $\theta = 2.9 \times 10^{-3}$ rad or 0.17 degrees.

Figure 7 shows the results for (a) the total charge $N$, (b) central density $n_0$ and (c) plasma radius $r_P$ for five values of δ (color coded). Displayed here are measurements for $t_{\text{hold}} \geq 0.5 \text{s}$. For earlier hold times, the camera image was saturated, preventing an accurate measurement of the central density. This is due to the camera and phosphor screen settings. They are constant for all measurements and chosen to enable the evaluation of the plasma profiles at larger confinement times. At 0.5 s, the central density and radius have already changed from their initial values: the radius has substantially increased from the initial 0.5 mm, and with it, the central density is reduced. This radial expansion and reduction of the central density is monotonically increasing with the misalignment $\delta$. The number of particles stays constant up to 10 s, except for the cases with $\delta = 213 \mu$m and 350 μm. Here the plasma has already lost charge after 5 s and 2 s respectively. For $\delta > 350 \mu$m, no data are available due to mechanical constraints on δ.

In a positron storage application, one would use the rotating wall technique (RW) (Danielson & Surko 2006a) to inhibit plasma expansion, but the RW must be turned off for some plasma manipulations. The measurements indicate this could be done without the RW for 2 s to 5 s without loss of particles for this range of misalignments. Minimum expansion is important, because RW compression will be applied for long-term particle confinement in the MCT, and the RW works best when the plasma is well confined, i.e. the radial extend of the plasma is small compared to the electrode inner radius. As shown in Fig. 7(c), this favors good alignment.

Over the course of the measurement, the plasma radius stays small compared to the wall radius, i.e. $r_P < r_W = 6$ mm, albeit losing charge. We suspected that this might be correlated to a plasma ‘halo’ that was observed to form at large hold times in a previous experiment (Hurst et al. 2019). To check this assumption, Fig. 8 displays the angularly averaged plasma profiles for different hold times (color coded) and for two alignment cases: (a) the best aligned case with $\delta = 3 \mu$m and (b) a case with a misalignment of $\delta = 260 \mu$m. Both cases start with a similar amount of charge and the hold times are chosen so that the charge is constant for all of them except for $t_{\text{hold}} = 100 \text{s}$ [see Fig. 7(a)]. In both cases there are defects on the screen. These defects lead to an increased background at radii from 2.7 mm to 4.1 mm in (a), and from 1.6 mm to 3.1 mm in (b). The usual noise floor of these profiles is $\sim 1 \times 10^6$.

Magnetic field considerations for a multi-cell Penning-Malmberg trap for positrons

Figure 7. Confinement as a function of the hold time $t_{\text{hold}}$ in s for different alignments of storage cell S$_{2,2}$, where $\delta$ (color coded) is the displacement of the centers of electrodes S$_{2,2}$ and S$_{2,5}$ in $\mu$m; (a) number of particles $N$ and (b) central density $n_0$ in arbitrary units; and (c) plasma radius $r_p$ in mm. The dotted lines are included to guide the eye.

Figure 8. Angularly averaged radial profiles for different hold times and two different misalignments; (a) the best aligned case $\delta = 3 \mu$m and (b) with a misalignment of $\delta = 260 \mu$m. There are defects on the screen which lead to an increased background at radii (a) from 2.7 to 4.1 mm, and (b) from 1.6 to 3.1 mm. The noise floor is $1 \times 10^0$.

In Fig. 8(a), at $t_{\text{hold}} = 0.23$s the profile is a Gaussian with the maximum saturated. For increasing hold times, the central density decreases monotonically. At 1.03 s a second feature appears in the profile. It is visible as a step in the profile at a radius of $\sim 0.5$ mm and grows more prominent with increasing hold time. From 1.03 s to 5.03 s, while the central amplitude continues to drop, the step in the profile moves outward radially. At $t_{\text{hold}} = 10$s the step in the profile has nearly vanished. A 'halo' (i.e. low-density region)
has formed surrounding the plasma core. These halos are associated with increased transport (Hurst et al. 2019). With further increased hold time, this halo moves radially outwards until it reaches the wall, resulting in a loss of charge. At 100.03 s, after halo plasma is lost to the wall, the plasma profile takes on a flap-top shape, indicating that it has reached a steady state. However, a small step is visible in the profile at 1.4 mm radius. The significance of this feature in the profile is currently unclear.

The temporal behaviour of the plasma profiles in Fig. 8(b) is the same as in (a): The central peak decreases monotonically with the hold time. About 1.03 s a halo begins to form around the central peak which slowly moves outward radially. The misalignment affects this behaviour in that increasing $\delta$ increases the rate at which the central peak drops and the halo moves outward radially. Comparing the final profiles at $t_{\text{hold}} = 100$ s in (a) and (b), we see that an increased misalignment leads to a decrease in the central amplitude by a factor of 2, and an increase in the plasma radius. Both profiles display a flat-top shape which is expected for a thermalized noneutral plasma in a PM trap (Driscoll et al. 1988; Dubin & O’Neil 1999; Danielson et al. 2015). The step at the plasma edge is a bit more prominent for $\delta = 260 \mu$m, suggesting that the halo formation might be increasing with $\delta$. However, the overlap of this region in Fig. 8(b) with the screen’s defects prevents a definite conclusion.

For a practical MCT for $N \geq 10^{10}$ particles, the plasma length should be $\simeq 200$ mm. Thus, if it is the maximum deviation of plasma from the magnetic axis which matters for good confinement, then the angular tolerance would be $\sim 3$ times smaller than that for the 69 mm long alignment distance relevant to Fig. 7. Assuming a $\delta = 203 \mu$m misalignment, this would correspond to $\theta \sim 1.0 \times 10^{-3}$ rad for a 200 mm long plasma.

These misalignments were compared with the degree to which the field is bent (as per Eq. 3.3) using the COMSOL model of the magnet (Table 1, Case 4), and the results are shown in Fig. 9. The error in the model is low ($\lesssim 4$ mT) in the range $z = \pm 200$ mm where the electrodes are placed.

The model is used to investigate the B-field profile on and off-axis as was done for the other cases in Table 1. Figure 9 shows the $r$ and $z$ components of B as well as the deviations of the field lines calculated with Eq. 3.5. The higher resolution of Fig. 9 (b)
Magnetic field considerations for a multi-cell Penning-Malmberg trap for positrons

shows the $B_z$ profile with maxima at different $z$ values for different radial locations. Figures 9(c) and (d) show the radial field and corresponding field line curvature for the model which is similar in amplitude to that of the Case 2, although with a shorter region of uniformity. Beyond $\pm \sim 140$ mm, the field falls off sharply.

The optimum confinement region for this model is thus limited to $\pm \sim 120$ mm from the center in order to exclude magnetic maxima. Using Eq. 3.5, the angular deviation of the $r = 50$ mm field line from $z = [0, 120]$ mm is $\theta = 9.4 \times 10^{-5}$ rad, which is close to the minimum measurable value reported in Ref. (Singer et al. 2021). If the on-axis confinement results are valid off-axis, the field line bending is sufficiently small as to not present a problem and even has a safety factor of $\sim 4$ for a 200 mm long plasma.

6. Summary and concluding remarks

Presented here are the considerations relevant to the design of a solenoid optimized for a multicell trap for the accumulation of large numbers of positrons. Since the MCT architecture requires PM cells both on and off the magnetic axis, the required magnetic field is further constrained beyond that required for on-axis PM traps. For good confinement, the magnetic field lines should be straight and parallel to the axes of the cylindrical confining electrodes.

Assuming that magnetically trapped particles are an important consideration for good confinement, there should also be no magnetic field maxima (i.e., “magnetic mirrors”) in the confinement region. To ensure the absence of these maxima, the magnetic field is tailored to avoid maxima in the confinement region, which results in a radial component of $B$ and hence some field-line bending. While this effect is absent on axis, it can be important for off-axis storage cells, such as those required in present MCT designs.

While electrostatic particle trapping is also an important consideration for good confinement, it has not been considered here. Also not considered here are added coils that would be necessary to shield the magnetic field far from the confinement region to mitigate deleterious effects on nearby apparatus and beam lines. This could be done by configurations such as those described in Li et al. (2020).

A design is presented for a 5 T magnet which eliminates magnetic mirrors by arranging a small positive spatial curvature of the magnetic field, and this results in an acceptably small amount of field-line deviation. There are two caveats to this design. This coil configuration is almost certainly not unique in producing an acceptable magnetic field structure for good particle confinement. Further, for the coil designs presented Table 1, little consideration has been given to practical construction details beyond simple estimates of acceptable forces on magnet coils and the tension in superconducting coil windings.

One consideration is discussed here, that to our knowledge has been neglected in previous work. This relates to the fact that field line bending in PM traps due to finite $\partial B/\partial z$ should, in principle, lead to enhanced particle transport (i.e., beyond the simple misalignment of straight field lines in the confinement electrodes). This would benefit from further theoretical and experimental work.

Also presented were data for electron confinement in a storage cell as a function of the alignment of the electrodes with respect to the magnetic axis. Among other results, this study highlights the importance of the low-density 'halo' plasma between the core plasma and the electrode wall. More extensive studies of these effects, and particularly confinement in off-axis cells, will be necessary to optimize the design of a high-capacity MCT.
